Abstract

The aim of this study was understanding the conventional physical therapy for improving the upper extremity functions of spastic ischemic stroke. This is a literature study with book, articles and papers. We consider the upper extremity function of spastic ischemic stroke can be improved with physical therapy which can promote healing process. So as to improve the upper extremity functions of the patient, a systematic approach of various methods is required.

Keywords: Ischemic stroke, Spasticity, Upper extremity function, Physical therapy

1. Introduction

Many people suffer long-term sequelae after stroke and have difficulty in performing independent activities because of the loss of functional abilities. Most stroke patients experience impairment of upper extremity motor skills, and 80% of hemiplegic patients experience hand function disorder [1][2][3]. The deterioration of the upper limb functions in stroke patients is associated with the spasticity of the upper extremities. The spasticity of the upper extremities mostly appears 1 year after stroke, which acts as a critical factor that interferes with the independent life of stroke patients [4]. Spasticity is a general characteristic of the upper motor neuron syndrome and ischemic stroke. A fast joint movement in spastic ischemic stroke patients increases the tension of the muscle by stretch reflex, which reinforces the jerk phenomenon of tendons; thus, it is a movement that should be avoided by spastic patients.

According to the Health Insurance Review and Assessment Service, there are 486,000 patients who are receiving treatment for ischemic stroke in South Korea. According to a study of Wizzle, spasticity develops within 6 weeks after onset in one in four stroke patients, primarily in the humeroulnar joint (79%), radiocarpal joint (66%), and tibiotarsal joint (66%) [5]. It has been reported that the spasticity pattern in the upper extremities appeared as medial rotation and adduction of the shoulder, flexion of the elbow, and flexion of the wrist and fingers in the upper extremities, and the adduction and extension of the knee and equinovarus of the foot in the lower extremities [5][6]. Another study reported that spasticity of the upper

Article history:

extremities appears within the first 1 year in 4% to 38% of stroke patients, and impairment of the arm function appears in 25% to 46% [7][8][9].

Unlike the lower extremities, the upper extremities have many functional aspects and play critical roles in functional daily living activities, such as eating, bathing, dressing, using the toilet, washing face, and taking a shower, and special functional activities, such as using a computer and writing. Securing the upper extremity function is critical because stroke patients with bilateral paralysis must lead daily life by making the best of the upper extremity functions.

The current treatments applied to stroke patients include medication, Transcutaneous Electrical Nerve Stimulation (TENS), Functional Electrical Stimulation (FES), traditional physical therapy such as stretching to improve the viscoelasticity of muscles, task-oriented training to enhance functional performance, and orthoses to prevent muscle shortening. However, there are still limitations in the physical therapy approach to recover the upper limb functions of spastic stroke patients. Therefore, this study reexamined various literatures because it is necessary to understand the upper extremity functions of spastic stroke patients, and a physical therapy approach is required to recover the upper extremity functions of these patients.

2. Main discourse

2.1. Occurrence of spastic ischemic stroke

Only a few studies have addressed the occurrence of spasticity. Somerfield [10][11] conducted the Modified Ashworth Scale (MAS) test for 95 first-stroke patients and found that spasticity appeared in 21% of all patients and 26% of 77 hemiplegic patients within 5.4 days on average. Furthermore, spasticity appeared within 3 months in 19% of the 95 subjects and in 28% of 64 patients who still had hemiplegia. The MAS scores of the patients stayed the same in most cases in 5 days and 3 months after onset, and only one patient changed from 1 to 4 points. These results suggest that the prevalence in all patients did not increase from 5 days to 3 months, but only increased slightly in the hemiplegia group.

According to a recent study, the morbidity rate of spasticity was not much different between the upper and lower extremities, but severe spasticity cases mostly appeared in the upper extremities [12]. However, severe cases of spasticity are very rare.

2.2. Pathology of the upper extremities of spastic ischemic stroke patients

Spasticity of stroke patients is caused by the collapse of the relationship between sensory input and motor response, which leads to hypersensitive reaction of the compartmentalized central nervous system [12]. This is related to the intensity of the input sense, such as the strength of stretching, and to the location of damage in the central nervous system. If the balance between the inhibitory and excitatory nerve fibers is broken, various syndromes of the upper extremities can appear, such as hypotonia, dyskinesia, and spasticity. Spasticity is caused when there is a damage of the brain stem, the primary, secondary, and subsidiary movement regions of the cerebral cortex, and area 3 of the pyramidal tract of the spinal cord [13]. The occurrence of spasticity can be explained by the reorganization of disorderly nerves after the brain is damaged.

2.3. Assessment of spastic ischemic stroke patients
(1) Modified Ashworth Scale

The MAS is a method of measuring the degree of resistance of passive motions. It cannot measure the passive motion speed of joints, angle of muscle contraction, and degree of potential resistance of tendons. The MAS is an assessment method that can be easily used in clinical practice and is widely used in many studies. However, it showed an average degree of reliability in validation research [14]. The reliability of the MAS is limited if the joint motions are reduced by contracture and is not affected by the joint movement speed. However, the MAS is established for assessing the contracture of the soft tissue and the combination of spastic myopathy and spasm [15][16].

(2) Modified Tardieu Scale

The Modified Tardieu Scale (MTS) is an assessment method for the passive joint motion speed and potential resistance of tendons. This assessment method classifies spasticity into three levels of speed: low, normal, and fast. It is a more accurate indicator than the MAS. The MTS is more sensitive because the muscle resistance and speed are measured after muscle contraction [17].

2.4. Physical therapy of the upper extremity in spastic ischemic stroke patients

(1) Basics of Physical Therapy

The basic principle of physical therapy for spastic patients is that limiting the muscle contracture and reducing over-activity at least for a short period can help them. The purpose of stretching is to enhance the viscoelasticity of muscles and tendons and increase the extensibility. However, stretching can increase the tension of the surrounding tissues, such as blood vessels, skin, connective tissues, and nerve tissues. The applied strength, time, speed, and frequency of stretching have not been agreed upon yet. A recent study systematically examined the effect of stretching to remove the muscle contracture of brain-damaged patients and concluded that stretching did not cause a significant change in joint mobility, pain, spasticity, or limitation of activity [18].

Other physical therapy methods are used to reduce spasticity and improve motor function. Hydrotherapy, cryotherapy, hyperthermia, vibration stimulation, inhibition of neurodevelopment, and treatment with a robot are used to relax muscles and lower the intensity of spasticity.

(2) Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT) is an exercise intervention developed on the basis of the learned nonuse model and cortical relocation phenomenon. It enforces the use of the affected side by prohibiting the use of the unaffected side. The unaffected side is restricted for 90% of the wake time for 2 weeks, and intensive and repeated training is performed on the affected side [18].

The advantage of CIMT is that it can induce improvement of functions and prevent pain and overuse syndrome caused by the overuse of the unaffected side because it allows patients to train themselves, train functional activities, suppress the unaffected side, and force patients to use the affected side. However, CIMT can cause psychological anxiety and burden because it is a high-intensity training program for patients. Furthermore, it is difficult to perform training for 6 hours in treatment facilities. It is also difficult to live everyday life because restriction of the unaffected side and psychological burden increase as a result.

(3) Orthoses

Orthoses are used to complement and assist physical therapy, reduce spasticity and pain, improve functions, give a sense of protection, and prevent deterioration. Their biggest advantage is that they have a long duration of effect because patients can be left for several hours without a therapist or nurse. However, orthoses have not been proved through a double-blind test, and no improvements were observed in the spasticity of the wrist flexion muscle or movement of the entire hand [19].

(4) Transcutaneous Electrical Nerve Stimulation

TENS is a physical therapy method that injects electric signals according to the site of spasticity and the skin nerve control level of the spinal cord. It is effective in reducing the spasticity of the antagonist muscle. The effect of TENS seems to be associated with the production of β-endorphin, which reduces the activity of the muscle. According to the gateway control theory, it appears to reduce the input of new information by adjusting the delivery of pain signal. It has been suggested that TENS can promote the reorganization of the cerebral cortex synapses and accelerate the exercise output by increasing the sensory input by stimulating the Aβ-tissue of the large-diameter nerve fibers [20]. More research is required.
to define the most effective parameters and describe the mechanism that forms the basis of this theory.

3. Conclusion

Geriatric diseases are increasing with the increasing elderly population globally as well as in South Korea. In particular, stroke is a very dangerous disease and is the second most common cause of deaths among single diseases. Furthermore, stroke causes large individual, social, and economic losses because of serious sequelae that interfere with the daily life after survival, and the quality of life of stroke patients is low as a result. The upper extremities are critical not only for the daily life of individuals but also for their social activities, and they are directly related to the work ability of individuals. Even though there are many treatments to enhance the upper limb functions of stroke patients, their therapeutic effects are not consistent. In the future, more diverse and systematic approaches to reinforce the arm and hand functions of stroke patients would be necessary.
